Objective. To provide evidence-based recommendations and expert guidance for the management of giant cell arteritis (GCA) and Takayasu arteritis (TAK) as exemplars of large vessel vasculitis.

Methods. Clinical questions regarding diagnostic testing, treatment, and management were developed in the population, intervention, comparator, and outcome (PICO) format for GCA and TAK (27 for GCA, 27 for TAK). Systematic literature reviews were conducted for each PICO question. The Grading of Recommendations Assessment, Development and Evaluation methodology was used to rate the quality of the evidence. Recommendations were developed by the Voting Panel, comprising adult and pediatric rheumatologists and patients. Each recommendation required ≥70% consensus among the Voting Panel.

Results. We present 22 recommendations and 2 ungraded position statements for GCA, and 20 recommendations and 1 ungraded position statement for TAK. These recommendations and statements address clinical questions relating to the use of diagnostic testing, including imaging, treatments, and surgical interventions in GCA and TAK. Recommendations for GCA include support for the use of glucocorticoid-sparing immunosuppressive agents and the use of imaging to identify large vessel involvement. Recommendations for TAK include the use of nonglucocorticoid immunosuppressive agents with glucocorticoids as initial therapy. There were only 2 strong recommendations; the remaining recommendations were conditional due to the low quality of evidence available for most PICO questions.

Conclusion. These recommendations provide guidance regarding the evaluation and management of patients with GCA and TAK, including diagnostic strategies, use of pharmacologic agents, and surgical interventions.
INTRODUCTION

Giant cell arteritis (GCA) and Takayasu arteritis (TAK) are systemic vasculitides that primarily affect large- and medium-sized vessels (1). GCA can present with both cranial and extracranial manifestations. Cranial manifestations include headaches, scalp tenderness, vision loss, and jaw claudication. Large vessel (“extracranial”) involvement results in arterial stenosis and aneurysms, causing absent pulses and limb claudication (2). GCA is more common in individuals of Northern European descent who are older than 50 years of age. Diagnosis is based on clinical presentation, pathologic abnormalities on temporal artery biopsy, and/or evidence of large vessel involvement on vascular imaging (1–6). Glucocorticoids are the mainstay treatment for GCA, but tocilizumab has been approved by the US Food and Drug Administration for the treatment of GCA (7,8).

TAK causes granulomatous inflammation of the aorta and its branches. It is more common in younger women (9,10). Clinical manifestations include constitutional symptoms, elevated levels of inflammation markers, and arterial stenosis and/or aneurysms resulting in limb claudication and absent pulses (11). Treatment options include glucocorticoids, nonglucocorticoid immunosuppressive agents, and surgical management of vascular abnormalities (12).

As GCA and TAK share clinical manifestations, similar questions arise regarding their treatment and management. Recent studies have broadened treatment options for GCA, and vascular imaging is increasingly used for diagnosis and management. This guideline was developed to provide evidence-based recommendations for the evaluation and management of GCA and TAK.

METHODS

This guideline followed the American College of Rheumatology (ACR) guideline development process (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines) using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology to rate the quality of evidence and develop recommendations (13–15). ACR policy guided the management of conflicts of interest and disclosures (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines/Vasculitis). Supplementary Appendix 1 (available on the Arthritis & Rheumatology website at http://onlinelibrary.wiley.com/doi/10.1002/art.41774/abstract) presents a detailed description of the methods. Briefly, the Literature Review team undertook systematic literature reviews for predetermined questions specifying the clinical population, intervention, comparator, and outcomes (PICO). An in-person Patient Panel of 11 individuals with different types of vasculitis (3 patients with GCA or TAK) was moderated by a member of the Literature Review team (ABD). This Patient Panel reviewed the evidence report (along with a summary and interpretation by the moderator) and provided patient perspectives and preferences about their personal experiences regarding clinical and treatment aspects of their disease. The Voting Panel comprised 9 adult rheumatologists, 5 pediatric rheumatologists, and 2 patients; they reviewed the Literature Review team’s evidence summaries and, bearing in mind the Patient Panel’s deliberations, formulated and voted on recommendations. A recommendation required ≥70% consensus among the Voting Panel.

The article is published simultaneously in Arthritis Care & Research. Supported by the American College of Rheumatology and the Vasculitis Foundation.

How to interpret the recommendations

A strong recommendation is typically supported by moderate- to high-quality evidence (e.g., multiple randomized controlled trials). For a strong recommendation, the recommended course of action would apply to all or almost all patients. Only a small proportion of clinicians/patients would not want to follow the recommendation. In rare instances, a strong recommendation may be based on very low- to low-certainty evidence. For example, an intervention may be strongly recommended if it is considered low-cost, without harms, and the consequence of not performing the intervention may be catastrophic. An intervention may be strongly recommended against if there is high certainty that the intervention will lead to more harm than the comparison with very low or low certainty about its benefit (16).

A conditional recommendation is generally supported by lower-quality evidence or a close balance between desirable and undesirable outcomes. For a conditional recommendation, the recommended course of action would apply to the majority of the patients, but the alternative is a reasonable consideration. Conditional recommendations always warrant a shared decision-making approach. We specify conditions under which the alternative may be considered.

In some instances, the committee found that the evidence for a particular PICO question did not support a graded recommendation or did not favor one intervention over another. However, the Voting Panel believed that the PICO question addressed a commonly encountered clinical question which has not been fully clarified and requires further investigation, and thus felt that providing guidance for this question was warranted. For these situations, we present “ungraded position statements,” which reflect general views of the Voting Panel.

In this evidence-based guideline, we explicitly used the best evidence available and present that in a transparent manner for the clinician reader/user (10). In some instances, this includes randomized trials in which the interventions under consideration are directly compared. The GRADE system rates evidence that comes exclusively from the collective experience of the Voting Panel and Patient Panel members as “very low- quality” evidence (15).

For each recommendation, details regarding the PICO questions and the GRADE evidence tables can be found in Supplementary Appendix 2 (http://onlinelibrary.wiley.com/doi/10.1002/art.41774/abstract).

RESULTS

For the GCA evidence report, 399 articles were reviewed to address 27 PICO questions. For the TAK evidence report, 347 articles were reviewed to address 27 PICO questions.

Recommendations and ungraded position statements for the management of GCA

Table 1 presents definitions of selected terms used in the recommendations, including disease states such as severe disease, dosing ranges for glucocorticoids, categorization of medications, and disease assessments. Tables 2 and 3 present the recommendations with their supporting PICO questions and levels of evidence. We present 22 recommendations and 2 ungraded position statements for GCA. All but 1 of the recommendations are conditional due to very low- to low-quality evidence. Figure 1 presents key recommendations for the treatment of GCA.

Diagnostic testing

Recommendation: For patients with suspected GCA, we conditionally recommend an initial unilateral temporal artery biopsy over bilateral biopsies.

Initially, a unilateral biopsy is recommended. However, bilateral temporal artery biopsies may be appropriate if the symptoms are not clearly localized to 1 temporal artery. Proceeding with the contralateral biopsy is also appropriate if the unilateral biopsy result is negative and additional evidence for cranial GCA is sought (17).

Recommendation: For patients with suspected GCA, we conditionally recommend a long-segment temporal artery biopsy specimen (>1 cm) over a short-segment temporal artery biopsy specimen (<1 cm).

A longer segment of the temporal artery is preferred, since GCA is a focal and segmental disease, and the added morbidity of obtaining a larger segment is very low. A shorter segment obtained on biopsy can result in reduced diagnostic yield and a missed diagnosis. This recommendation is conditional due to a lack of high-quality evidence, but the Voting Panel emphasized obtaining longer biopsy specimens when possible (18,19).

Recommendation: For patients with suspected GCA, we conditionally recommend obtaining a temporal artery biopsy specimen within 2 weeks of starting oral glucocorticoids over waiting longer than 2 weeks for a biopsy.

Overall, biopsy specimens should be obtained as soon as possible to maximize the likelihood of detecting histopathologic changes. Studies suggest that histopathologic changes indicating GCA are more likely to be detected in a temporal artery biopsy if obtained within 2 weeks of starting glucocorticoids; however, histopathologic changes have been detected in biopsy specimens obtained much later than 2 weeks after the start of glucocorticoid treatment (20–28). A biopsy specimen obtained 2 weeks after starting glucocorticoids could be informative and may be considered at the discretion of the physician and patient.

Recommendation: For patients with suspected GCA, we conditionally recommend temporal artery biopsy over temporal artery ultrasound for establishing a diagnosis of GCA.

In general, rheumatologists and radiologists in the US are less experienced in using ultrasound to diagnose temporal artery involvement in GCA compared to their counterparts in Europe. Therefore, temporal artery biopsy remains the optimal approach to diagnosing GCA in the US, because ultrasound is operator-dependent and results are influenced by treatment (i.e., signs of inflammation quickly disappear with glucocorticoid treatment). In centers with appropriate training and expertise in using temporal artery ultrasound, ultrasound may be a useful and complementary tool for diagnosing GCA (29–33).

* For the population, intervention, comparator, and outcome (PICO) questions used in the Grading of Recommendations Assessment, Development and Evaluation methodology, as developed for giant cell arthritis (GCA), please refer to Supplementary Appendix 2 (available on the Arthritis & Rheumatology website at http://onlinelibrary.wiley.com/doi/10.1002/art.41774/abstract). GCs = glucocorticoids; IV = intravenous; HMG-CoA = hydroxymethylglutaryl-coenzyme A.
† PICO question was developed after completion of literature review and evidence reports. Data from studies already included in evidence reports were reviewed, but no dedicated literature review was performed for these questions. Recommendation was formed from available evidence and expert opinion.
‡ Ungraded position statement was not based on a specific PICO question.

**Recommendation: For patients with suspected GCA, we conditionally recommend temporal artery biopsy over magnetic resonance imaging (MRI) of the cranial arteries for establishing a diagnosis of GCA.**

Protocols to image the cranial vessels using different modalities, including MRI, have been developed, which can be helpful to establish a diagnosis of GCA (30,31,34–37). However, lack of technical expertise with this modality in the US, as well as the lack of widespread validation of this approach, limits the applicability of MRI with contrast of the cranial vessels as a replacement for temporal artery biopsy at the current time.
Recommendation: For patients with suspected GCA and a negative temporal artery biopsy result (or results), we conditionally recommend noninvasive vascular imaging of the large vessels with clinical assessment to aid in diagnosis over clinical assessment alone.

Imaging the large vessels may provide additional evidence of disease (e.g., extracranial GCA) when the diagnosis is uncertain following negative temporal artery biopsy results (28,34,38–44). Potential diagnostic imaging modalities include MR or computed tomography (CT) angiography of the neck/chest/abdomen/pelvis, ultrasonography, and 18F-fluorodeoxyglucose positron emission tomography (FDG-PET) (43,45).

Recommendation: For patients with newly diagnosed GCA, we conditionally recommend obtaining noninvasive vascular imaging to evaluate large vessel involvement.

Baseline noninvasive imaging with MR or CT angiography of the neck/chest/abdomen/pelvis in patients with newly diagnosed GCA can detect large vessel involvement and may be compared with subsequent routine monitoring if indicated (46). In a patient with large vessel involvement, routine noninvasive vascular imaging can identify early and long-term complications, such as aneurysms and stenoses, and assess stability of existing lesions. In patients without large vessel involvement, routine and repeated monitoring with vascular imaging may or may not be necessary.

Medical management

Recommendation: For patients with newly diagnosed GCA without manifestations of cranial ischemia, we conditionally recommend initiating treatment with high-dose oral glucocorticoids over intravenous (IV) pulse glucocorticoids.

Cranial ischemic manifestations include visual and neurologic involvement such as amaurosis fugax, vision loss, and stroke. Some studies have suggested that the use of IV pulse glucocorticoids in this patient group could decrease disease relapse and increase remission rates. However, routine use of IV pulse glucocorticoids can also be associated with increased risks, including infections, that may outweigh the benefits, especially in the elderly (47,48).

Recommendation: For patients with newly diagnosed GCA with threatened vision loss, we conditionally recommend initiating treatment with IV pulse glucocorticoids over high-dose oral glucocorticoids.

Studies investigating the effect of IV pulse glucocorticoids in patients with GCA and cranial ischemia have demonstrated conflicting results. However, this population is at high risk for vision loss as well as toxicity from glucocorticoid use. IV pulse glucocorticoids can be used in patients with the highest risk of vision loss, but this decision should be guided by the patient’s clinical condition, values, and preferences (49,50).
Recommendation: For patients with newly diagnosed GCA, we conditionally recommend dosing oral glucocorticoids daily over an alternate-day schedule.

This recommendation is conditional solely due to the low level of evidence, which indicates higher remission rates in patients receiving daily dosing. The panel did not identify any situations in which alternate-day dosing of prednisone would be preferred (51).

Recommendation: For patients with newly diagnosed GCA, we conditionally recommend initiating treatment with high-dose oral glucocorticoids over moderate-dose oral glucocorticoids.

We recommend starting high-dose oral glucocorticoids to achieve rapid disease control followed by tapering the glucocorticoid dose (weeks to months) to avoid prolonged high-dose treatment and reduce toxicity. The dosing and duration of oral glucocorticoid therapy can be variable depending on a patient’s manifestations and comorbidities and whether the use of a glucocorticoid-sparing agent was also initiated. Studies supporting the efficacy and lower toxicity of moderate-dose glucocorticoids are of low quality, which prevents the Voting Panel from recommending moderate-dose glucocorticoids as initial therapy. Moderate-dose glucocorticoids may be used in patients with significant risk of severe glucocorticoid toxicity and in patients with low risk of vision loss or other life- or organ-threatening complications (48–53).

Recommendation: For patients with newly diagnosed GCA, we conditionally recommend the use of oral glucocorticoids with tocilizumab over oral glucocorticoids alone.

A trial published in 2017 (8) demonstrated that tocilizumab has a significant glucocorticoid-sparing effect in GCA, and thus, tocilizumab should be considered for initial treatment. However, methotrexate with glucocorticoids, as well as glucocorticoids alone, can also be considered as initial treatment for newly diagnosed GCA. The decision to treat with tocilizumab and glucocorticoids, methotrexate and glucocorticoids, or glucocorticoid monotherapy for initial therapy should be made based on the physician’s experience and the patient’s clinical condition, values, and preferences. Lack of long-term follow-up data on tocilizumab and cost may limit its use (8,54). Abatacept with glucocorticoids can also be considered if these other agents are not effective (55).

Recommendation: For patients with GCA with active extracranial large vessel involvement, we conditionally recommend treatment with oral glucocorticoids combined with a nonglucocorticoid immunosuppressive agent over oral glucocorticoids alone.

Management of GCA in patients with new, persistent, or worsening extracranial symptoms (e.g., limb claudication) or signs (e.g., imaging findings) attributed to GCA can include the addition of nonglucocorticoid immunosuppressive agents. These agents include biologic agents (e.g., tocilizumab) as well as oral therapies (e.g., methotrexate) (56,57). However, the Voting Panel recognizes that there are few high-quality studies evaluating the efficacy of these agents for this patient group. While there is stronger clinical evidence supporting the use of tocilizumab compared to methotrexate for the treatment of GCA, methotrexate can be considered for patients unable to use tocilizumab due to factors such as recurrent infections, history of gastrointestinal perforations or diverticulitis, and cost.

Ungraded position statement: The optimal duration of therapy with glucocorticoids for GCA is not well established and should be guided by the patient’s values and preferences.

Factors that may influence the duration of therapy include the patient’s clinical manifestations, toxicity related to glucocorticoid use, number of flares, the physician’s experience, and the patient’s preferences (8). Overall, the Patient Panel emphasized minimizing the use of glucocorticoids as much as possible but recognized that longer-term use may be needed in some patients to avoid flares.

Recommendation: In patients with newly diagnosed GCA, we conditionally recommend against the use of a hydroxy methylglutaryl-coenzyme A reductase inhibitor (“statin”) specifically for the treatment of GCA.

The use of statins is not known to provide a clinically significant immunosuppressive effect for GCA. Whether statins are warranted to decrease the patient’s risk of cardiovascular events is a separate clinical question and depends on the patient’s risk factors for cardiovascular disease (58–60).

Recommendation: For patients with GCA who have critical or flow-limiting involvement of the vertebral or carotid arteries, we conditionally recommend adding aspirin.

There are few data regarding this clinical question, but the antiplatelet activity of aspirin may be beneficial in preventing ischemic events in patients with vascular narrowing causing decreased cerebral blood flow (61–64). The efficacy of aspirin to prevent ischemic events in patients without vertebral or carotid narrowing remains unclear at this time.

Recommendation: For patients with GCA who experience disease relapse while receiving moderate- to- high- dose glucocorticoids, we conditionally recommend adding a nonglucocorticoid immunosuppressive drug.

Relapses of any type while receiving moderate- to- high-dose glucocorticoids indicate that it is unlikely that it will be possible for glucocorticoids to be tapered to a low dose. Therefore, glucocorticoid-sparing therapy should be considered.
Recommendation: For patients with GCA who experience disease relapse with symptoms of cranial ischemia, we conditionally recommend adding a nonglucocorticoid immunosuppressive agent and increasing the dose of glucocorticoids over increasing the dose of glucocorticoids alone.

Nonglucocorticoid immunosuppressive agents considered in this situation include tocilizumab and methotrexate (8,65,66). Relapses with symptoms of polymyalgia rheumatica may be controlled by increasing the dose of glucocorticoids alone.

Recommendation: For patients with GCA who experience disease relapse with cranial symptoms while receiving glucocorticoids, we conditionally recommend adding tocilizumab and increasing the dose of glucocorticoids over adding methotrexate and increasing the dose of glucocorticoids.

Tocilizumab is an effective glucocorticoid-sparing agent for GCA (8,54). While there are no comparative studies, the glucocorticoid-sparing effect seen with methotrexate is smaller than the effect seen with tocilizumab (8,55,65–67). While the glucocorticoid-sparing effect of tocilizumab is best quantified using the subcutaneous formulation (8), IV tocilizumab has also been shown to be glucocorticoid-sparing (54). Again, methotrexate can be considered for patients who are unable to tolerate or have limited access to tocilizumab.

Surgical intervention

Ungraded position statement: For any patient requiring surgical vascular intervention for GCA, the type and timing of intervention should be a collaborative decision between the vascular surgeon and rheumatologist.

Recommendation: For patients with severe GCA and worsening signs of limb/organ ischemia who are receiving immunosuppressive therapy, we conditionally recommend escalating immunosuppressive therapy over surgical intervention with escalation of immunosuppressive therapy.

Because patients can develop collateral blood vessels to improve distal blood flow, immunosuppressive therapy is recommended as initial therapy in patients with GCA and worsening limb/organ ischemia. However, clinical situations that would warrant consideration of immediate surgical intervention include aortic aneurysms at high risk for rupture and impending/progressive tissue or organ infarction or damage (68–70).

Recommendation: For patients with GCA undergoing vascular surgical intervention, we conditionally recommend the use of high-dose glucocorticoids during the periprocedural period, if the patient has active disease.

This recommendation pertains to patients with GCA who are undergoing a vascular surgical intervention due to a complication of GCA (e.g., aneurysm or stenosis). There are limited data regarding the use of high-dose glucocorticoids during the periprocedural period in GCA, and thus, support for this recommendation is based in part on their use in TAK. As in TAK, high doses of oral glucocorticoids in the perioperative setting are recommended if the disease is active or if the clinician is concerned that the patient may have active disease.

Clinical/laboratory monitoring

Recommendation: For patients with GCA in apparent clinical remission, we strongly recommend long-term clinical monitoring over no clinical monitoring.

The optimal frequency and length of monitoring are not well established and depend on factors including the duration of remission, site of involvement, risk of disease progression, whether the patient is receiving immunosuppressive therapy, and reliability of the patient to report new signs or symptoms (48,69). Clinical monitoring may include history taking, examinations, and laboratory and imaging studies. This is a strong recommendation given the minimal risks and potential catastrophic outcomes if monitoring is not performed.

Recommendation: For patients with GCA who have an increase in levels of inflammation markers alone, we conditionally recommend clinical observation and monitoring without escalation of immunosuppressive therapy.

Increases in levels of inflammation markers such as erythrocyte sedimentation rate and C-reactive protein can be nonspecific (69). Therefore, increasing immunosuppressive therapy is not warranted in the setting of increased levels of inflammation markers in the absence of other signs of disease activity. However, these increased levels may warrant more frequent clinical and/or radiographic assessments for active disease.

Recommendations and ungraded position statement for the management of TAK

Table 1 presents definitions of selected terms used in the recommendations, and Tables 4 and 5 present the recommendations with their supporting PICO questions and levels of evidence. We present 20 recommendations and 1 ungraded position statement for TAK. All recommendations except for 1 are conditional due to the availability of only very low– to low-quality evidence. Figure 2 presents key recommendations for the treatment of TAK.

Medical management

Recommendation: For patients with active, severe TAK who are not receiving immunosuppressive therapy, we conditionally recommend initiating treatment with high-dose oral glucocorticoids over IV pulse glucocorticoids followed by high-dose oral glucocorticoids.

There is no evidence that IV pulse glucocorticoids are more effective than high-dose oral glucocorticoids in this setting.
IV pulse glucocorticoids may be considered for patients with life- or organ-threatening disease. In children, alternate steroid dosing regimens (e.g., IV pulse glucocorticoids with low daily oral dosing) may be preferred to improve compliance and potentially reduce adverse consequences such as impacting growth (71).

**Recommendation:** For patients with newly active, severe TAK, we conditionally recommend initiating treatment with high-dose glucocorticoids over low-dose glucocorticoids.

A higher dose of glucocorticoids is recommended due to the potential for organ damage or life-threatening events. However, lower doses of glucocorticoids may be considered for patients with newly active, nonsevere disease (e.g., patients with constitutional symptoms and without limb ischemia) (72).

**Recommendation:** For patients with TAK who achieved remission while receiving glucocorticoids for ≥6–12 months, we conditionally recommend tapering off glucocorticoids over long-term treatment with low-dose glucocorticoids for remission maintenance.

The optimal duration of glucocorticoid use in TAK is unknown. Glucocorticoid exposure should be limited if possible in order to minimize toxicity. Glucocorticoids may be continued for a longer duration if disease is not adequately controlled or if the patient experiences frequent disease relapse.

GCs = glucocorticoids; IV = intravenous.
† Ungraded position statement was not based on a specific PICO question.
Recommendation: For patients with active TAK, we conditionally recommend the use of a nonglucocorticoid immunosuppressive agent plus glucocorticoids over glucocorticoids alone.

Nonglucocorticoid immunosuppressive agents are recommended over monotherapy with glucocorticoids to minimize glucocorticoid-related toxicity. Methotrexate is often used as the initial nonglucocorticoid immunosuppressive agent, but other therapies such as tumor necrosis factor inhibitors and azathioprine can be considered as well (70–73). Methotrexate is often preferred for use in children since it is usually well tolerated. Glucocorticoid monotherapy can be considered for mild disease or if the

* For the population, intervention, comparator, and outcome (PICO) questions used in the Grading of Recommendations Assessment, Development and Evaluation methodology, as developed for Takayasu arteritis (TAK), please refer to Supplementary Appendix 2 (available on the Arthritis & Rheumatology website at http://onlinelibrary.wiley.com/doi/10.1002/art.41774/abstract).

**Recommendation:** For patients with active TAK, we conditionally recommend the use of a nonglucocorticoid immunosuppressive agent plus glucocorticoids over glucocorticoids alone.

Nonglucocorticoid immunosuppressive agents are recommended over monotherapy with glucocorticoids to minimize glucocorticoid-related toxicity. Methotrexate is often used as the initial nonglucocorticoid immunosuppressive agent, but other therapies such as tumor necrosis factor inhibitors and azathioprine can be considered as well (70–73). Methotrexate is often preferred for use in children since it is usually well tolerated. Glucocorticoid monotherapy can be considered for mild disease or if the
diagnosis is uncertain. Patient-specific factors such as alcohol use, plans for childbearing, medication compliance, and medical comorbidities may influence the choice of immunosuppressant (73,74).

Recommendation: For patients with active TAK, we conditionally recommend the use of other nonglucocorticoid immunosuppressive therapy over tocilizumab as initial therapy.

As discussed above, nonglucocorticoid immunosuppressive agents such as methotrexate, tumor necrosis factor inhibitors, and azathioprine can be used as initial therapy in TAK. We recommend these agents over tocilizumab for initial therapy, because the efficacy of tocilizumab in TAK is not established at this time. While tocilizumab has been shown to be efficacious for GCA, the primary efficacy end point was not achieved in the only randomized trial of tocilizumab in TAK conducted thus far (74,75). Tocilizumab may be considered for patients with inadequate response to other immunosuppressive therapies. Abatacept is not recommended, since it has been shown in a small randomized controlled trial to not be efficacious in TAK (74,76).

Recommendation: For patients with TAK that is refractory to treatment with glucocorticoids alone, we conditionally recommend adding a tumor necrosis factor inhibitor over adding tocilizumab.

We recognize that among biologic therapies, some practitioners favor TNF inhibition, while others favor interleukin-6 inhibition (tocilizumab) in this situation. Overall, the Voting Panel favored tumor necrosis factor inhibitors over tocilizumab, since there is more clinical experience with and data on tumor necrosis factor inhibitors in TAK compared to tocilizumab. In observational studies, tumor necrosis factor inhibitors have been shown to induce remission and decrease relapses (77–79). Clinical experience with tocilizumab in TAK has been demonstrated in a randomized controlled trial and small case series. In the randomized trial, a trend toward a longer time to relapse was seen in the tocilizumab arm, but the difference was not statistically significant. However, that study was felt to be underpowered (36 participants). Of note, tocilizumab use also affects acute-phase reactants, which may impact ability to gauge disease activity. Therefore, while the panel favors tumor necrosis factor inhibitor use, we recognize that tocilizumab may also be considered, especially when tumor necrosis factor inhibitors are contraindicated (75).

Recommendation: For patients with TAK and asymptomatic progression of a previously identified vascular lesion seen on imaging, without evidence of inflammation, we conditionally recommend continuing current therapy over escalating/changing immunosuppressive therapy.

Vascular lesions can progress due to a number of factors that may not be related to active disease, such as "healing fibrosis" in response to effective treatment. Intervention is not always needed, since collateral circulation frequently develops over time. However, the location and the extent of the lesion of the affected vessel should be considered. Escalating immunosuppressive therapy may be warranted if significant progression has developed rapidly (e.g., weeks to months) after a period of stable disease (80,81).

Recommendation: For patients with active TAK and critical cranial or vertebrobasilar involvement, we conditionally recommend adding aspirin or another antiplatelet therapy.

Small observational studies suggest a decreased risk of ischemic events with antiplatelet therapy but an increased risk of bleeding (82). Therefore, antiplatelet therapy is usually used for patients at higher risk of ischemic events (e.g., patients with flow-limiting vertebrobasilar disease or stents). Antiplatelet therapy should be used with caution after surgical procedures or if there is an increased risk of bleeding (81).

Clinical/laboratory monitoring

Recommendation: For patients with TAK, we conditionally recommend adding inflammation markers to clinical monitoring as a disease activity assessment tool.

While inflammation markers are an imperfect indicator of disease activity, they may be helpful for clinical monitoring (80,83).

Recommendation: For patients with TAK in apparent clinical remission, we strongly recommend long-term clinical monitoring over no clinical monitoring.

The frequency of monitoring depends on factors including the duration of remission, sites of involvement, risk of disease progression, the patient’s immunosuppressive regimen, and the ability and likelihood of the patient reliably reporting new signs or symptoms of TAK. This is a strong recommendation given the minimal risks and potential catastrophic outcomes without monitoring (80,83).

Recommendation: For patients with TAK in apparent clinical remission but with an increase in levels of inflammation markers, we conditionally recommend clinical observation without escalation of immunosuppressive therapy.

As discussed above in the GCA recommendations, increases in levels of inflammation markers can be nonspecific, and intensifying immunosuppressive therapy in the setting of increased inflammation markers alone may not be warranted. More frequent clinical and/or radiographic assessments for active disease can be considered (77,80,83).
Vascular imaging

**Recommendation:** For patients with TAK, we conditionally recommend the use of noninvasive imaging over catheter-based dye angiography as a disease activity assessment tool.

Noninvasive imaging such as CT angiography, MR angiography, or FDG-PET are recommended because these imaging modalities provide information regarding vascular wall inflammation, while catheter-based angiography primarily provides information regarding the vascular lumen. Catheter-based angiography can be used to accurately determine central blood pressures, as part of surgical planning, or if noninvasive modalities do not provide adequate information. Identifying active disease based on noninvasive imaging at this time can be challenging, since the hallmarks of active disease have not been definitively established (43,45,84).

**Recommendation:** For patients with known TAK, we conditionally recommend regularly scheduled noninvasive imaging in addition to routine clinical assessment.

Routine imaging is recommended since vascular changes in TAK can occur when the disease is considered clinically quiescent. The optimal interval between imaging studies is not well established, and ranges vary (e.g., every 3–6 months or longer). The interval may be shorter early in the disease course and longer with established, quiescent disease. Since sedation may be required for imaging studies in children and can be associated with potential risks and complications, routine imaging of inactive disease in children is at the discretion of the treating clinician, while considering risks and benefits (85,86).

**Recommendation:** For patients with TAK in apparent clinical remission but with signs of inflammation in new vascular territories (e.g., new stenosis or vessel wall thickening) on vascular imaging, we conditionally recommend treatment with immunosuppressive therapy.

A new arterial stenosis is concerning as it can indicate recent active disease, and thus usually warrants immunosuppressive therapy. Other findings suggestive of active disease on MR angiography or CT angiography include vascular edema, contrast enhancement, and increased wall thickness, and may result in luminal damage over time. Findings of active disease by FDG-PET are defined by supraphysiologic FDG uptake in the arterial wall. However, abnormal findings in the vascular wall identified by imaging are not necessarily specific to vascular inflammation. The implication of finding vessel wall edema or enhancement on imaging remains an area of investigation, and the clinical importance of such findings on CT angiography, MR angiography, or FDG-PET is not certain (43,45,80,83–86). Therefore, all therapeutic decision-making in this context should occur after reviewing the imaging findings with a radiologist to help determine whether the observed imaging changes represent active disease.

**Surgical intervention**

Ungraded position statement: For any patient requiring surgical vascular intervention, the type and timing of intervention should be a collaborative decision between the vascular surgeon and rheumatologist.

**Recommendation:** In patients with known TAK and persistent limb claudication without evidence of ongoing active disease, we conditionally recommend against surgical intervention.

Patients with TAK can develop collateral circulation that bypasses the stenosis causing limb claudication, and thus, surgical intervention may not be needed (87). However, surgical intervention can be considered for patients whose activities are significantly impacted by limb claudication.

**Recommendation:** For patients with known TAK with worsening signs of limb/organ ischemia while receiving immunosuppressive therapy, we conditionally recommend escalating immunosuppressive therapy over surgical intervention with escalation of immunosuppressive therapy.

Immunosuppressive therapy is recommended to control vascular inflammation in order to improve or prevent worsening blood flow. However, clinical situations that could warrant immediate surgical intervention include coronary artery involvement and impending/progressive tissue or organ infarction (88–90).

**Recommendation:** For patients with TAK with renovascular hypertension and renal artery stenosis, we conditionally recommend medical management over surgical intervention.

Medical management includes antihypertensive drugs and immunosuppressive therapy if TAK is active. Surgical intervention (including catheter-based interventions) may be warranted for hypertension that is refractory to medical management in spite of optimized immunosuppressive therapy or in the setting of worsening renal function (12,91–94).

**Recommendation:** For patients with TAK and stenosis of a cranial/cervical vessel without clinical symptoms, we conditionally recommend medical management over surgical intervention.

Medical therapy is recommended if only a single vessel is involved, due to the substantial risks of surgery. Surgical interventions can be considered if multiple vessels are involved. This recommendation is based on indirect evidence obtained from neurologic experience and studies, because there is no direct evidence for TAK (90,95–98).
Recommendation: For patients with TAK with worsening signs of limb/organ ischemia, we conditionally recommend delaying surgical intervention until the disease is quiescent over performing surgical intervention while the patient has active disease.

Observational studies have suggested improved outcomes if surgical intervention is performed when disease is not active. However, surgical intervention during active disease may be necessary if the patient has life- or organ-threatening manifestations such as stroke, loss of viability of a limb, or myocardial ischemia (99–101). We recognize that determining the level of disease activity in TAK can be challenging.

Recommendation: For patients with TAK who are undergoing surgical intervention, we conditionally recommend the use of high-dose glucocorticoids in the periprocedure period if the patient has active disease.

This recommendation pertains to patients with TAK who are undergoing a vascular surgical intervention due to a complication of TAK. High doses of oral glucocorticoids in the periprocedural setting are recommended if the disease is active or if the clinician is concerned that the patient may have active disease (90,96,102).

DISCUSSION

This guideline presents the ACR/Vasculitis Foundation recommendations for the use of diagnostic testing, treatment, clinical and laboratory monitoring, and surgical intervention for patients with GCA or TAK. Overarching themes of the recommendations include the preference, in the US, for temporal artery biopsy over cranial imaging studies for the diagnosis of GCA, the use of large vessel imaging for GCA and TAK for diagnosis and disease monitoring, and limiting glucocorticoid exposure in order to minimize toxicity. Almost all recommendations are conditional due to low-quality evidence, reflecting the paucity of randomized clinical trials in these diseases.

Our recommendations regarding the use of temporal artery imaging differ from those presented by the European Alliance for Rheumatology (EULAR). In its recommendations regarding the use of imaging in large vessel vasculitis, EULAR indicates that the diagnosis of GCA may be made with a positive imaging test (e.g., temporal artery ultrasound or MRI of the cranial vessels), without additional testing such as temporal artery biopsy (103). However, the imaging recommendations presented by EULAR assume adequate expertise with these modalities. In the US, there is limited experience with temporal artery ultrasound and MRI of the cranial vessels as a diagnostic replacement for temporal artery biopsy, and thus, we continue to recommend temporal artery biopsy as the diagnostic test of choice at this time. However, we hope and anticipate that as experience with imaging of the temporal arteries to detect GCA (e.g., temporal artery ultrasound, MRI, and/or FDG-PET) increases in the US, patients will be able to benefit from these diagnostic tests. Also, in contrast to EULAR, we favor initial treatment of GCA with glucocorticoids and a glucocorticoid-sparing agent, given the well-recognized toxicity of glucocorticoids (104,105).

When reviewing the data abstracted for the PICO questions, it was clear that many critical clinical questions remain unanswered for GCA and TAK, and the lack of sufficient clinical evidence for these questions is reflected in the ungraded position statements presented in this guideline. For example, the optimal duration of therapy for any treatment and how best to monitor disease status is unknown. Few glucocorticoid-sparing agents have been identified through high-quality data. Accurate and validated indicators of disease activity have not been established or widely used for GCA or TAK. Interpretation of imaging studies in GCA and TAK can be challenging, and the clinical significance of persistent vascular wall inflammation during clinically quiescent disease is unclear.

Given these critical gaps in knowledge, we encourage additional research into the management of GCA and TAK. Studies that may greatly benefit patient care include the following: 1) translational studies contributing to the understanding of disease pathogenesis to facilitate development of more targeted therapies; 2) randomized clinical trials identifying new therapeutic options for the management of GCA and TAK; 3) randomized clinical trials comparing the effectiveness of currently used immunosuppressive therapies; and 4) longitudinal studies with biospecimen collection and routine vascular imaging to identify biomarkers of disease activity, indicators of disease prognosis, and the clinical sequelae of abnormalities identified on vascular imaging. We are hopeful that additional investigations into GCA and TAK will enable a more tailored approach to disease management in order to improve outcomes and minimize treatment toxicities.

ACKNOWLEDGMENTS

We thank Anne M. Ferris, MBBS, Ora Gewurz-Singer, MD, Rula Hajj-Al, MD, Eric Matteson, MD, MPH, Robert F. Spiera, MD, Linda Wagner-Weiner, MD, MS, and Kenneth J. Warrington, MD, for serving on the Expert Panel. We thank Antoine G. Sreih, MD and Gary S. Hoffman, MD, MS, for their contributions during the early phases of this project as members of the Core Team. Dr. Hoffman’s participation ended July 2018 due to personal reasons. Dr. Sreih’s involvement ended in December 2018 when he became primarily employed by industry, which precluded his continued participation in this project. We thank Joyce Kullman (Vasculitis Foundation) for her assistance with recruitment for the Patient Panel. We thank the patients who (along with authors Kathy A. Full and Omar I. Vitolajdli participated in the Patient Panel meeting; Jane Ascroft, Scott A. Brunton, Dedra DeMarco, Thomas Fitzpatrick, Jenni Gordon, Maria S. Mckay, Sandra Nye, Stephanie Saksen, and Ben Wilson. We thank Robin Arnold, Catherine E. Najem, MD, MSCE, and Anit Aakash Shah, MD, MPH, for their assistance with the literature review. We thank the ACR staff, including Ms Regina Parker, for assistance in organizing the face-to-face meeting and coordinating the administrative aspects of the project, and Ms Robin Lane for assistance in manuscript preparation. We thank Ms Janet Waters for help in developing the literature search strategy and performing the initial literature search, and Ms Janet Joyce for performing the update searches.
AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Drs.
